Abstract— As the size and number of wind power plants (WPP) increases, power system planners will need to study their impact on the power system in more detail. As the level of wind power penetration into the grid increases, the transmission system integration requirements will become more critical [1-2].

A very large WPP may contain hundreds of megawatt-size wind turbines. These turbines are interconnected by an intricate collector system. While the impact of individual turbines on the larger power system network is minimal, collectively, wind turbines can have a significant impact on the power systems during a severe disturbance such as a nearby fault. Since it is not practical to represent all individual wind turbines to conduct simulations, a simplified equivalent representation is required.

This paper focuses on our effort to develop an equivalent representation of a WPP collector system for power system planning studies. The layout of the WPP, the size and type of conductors used, and the method of delivery (overhead or buried cables) all influence the performance of the collector system inside the WPP. Our effort to develop an equivalent representation of the collector system for WPPs is an attempt to simplify power system modeling for future developments or planned expansions of WPPs. Although we use a specific large WPP as a case study, the concept is applicable for any type of WPP.

Index Terms—wind turbine, wind farm, wind power plant, wind energy, aggregation, equivalence, distribution network, collector system, power systems, systems integration, and renewable energy.

I. INTRODUCTION

Although it is very important to understand the dynamics of individual turbines [3-5], the collective behavior of the WPP and the accuracy in modeling the collector systems are also very critical in assessing WPP characteristics. Among other aspects, the design of collector systems for wind power plants seeks to minimize losses and voltage drops within budgetary constraints. This philosophy is generally applied regardless of the size of the WPP, the types of the turbines, and reactive power compensation.

Within a WPP, wind turbines are placed optimally to harvest as much wind energy as possible. Turbine layout in a large WPP on flat terrain is different from the layout of a WPP located on mountain ridges. Different layouts will have different impacts on the line impedances to the grid interconnection bus. Some preliminary work on equivalencing is based on single turbine representation [6].

Some WPPs are built with different types of wind turbines for different reasons. For example:

- recent unavailability of new turbines because wind turbine supply lags behind demand for wind turbines
- the economic benefit of mixing wind turbine types within the same WPP
- re-powering old WPPs with newer and bigger turbines.

When this problem arises, analysis of WPPs must take into account the fact that the WPP can no longer be represented by a single generator. Obviously, the representation must be based on several considerations, as will be discussed in section II.

This paper describes an analytical approach that can be used to derive the equivalent representation of a WPP collector system. Many textbooks on distribution system modeling are available [7], but this paper focuses on modeling WPP collector systems in particular. To illustrate the methodology, we used data from the proposed WPP to be built in Tehachapi, California, interconnected to the transmission grid owned and operated by Southern California Edison (SCE).

![Simplified one-line diagram of a typical wind power plant connected to a substation.](image-url)
Figure 1 shows a simplified one-line diagram for the single-machine equivalent of a WPP. For a very large installation, bus 1 is the point of interconnection connected to a step-up transformer that belongs to the 500-kV utility transmission system. Other projects are connected at 230 kV and the point of interconnection is at the bus 3 (low side of the substation transformer at 34.5 kV.

This paper is organized as follows: section II describes the steps we used to derive the equivalent impedance of a power system network. In section III, the technique of grouping wind turbines is presented. Section IV presents a case study representing WPP with multiple turbines. This paper is concluded in section IV. An additional Appendix is included that presents and tabulates the results of our calculations.

II. Step by Step Derivation

A. General overview and assumptions

In this section, we describe the background of the circuit simplification. A modern utility-size wind turbine generates electrical power at a low voltage level (typically 575 V or 690 V). Current utility-scale wind turbine ratings range from 1.5 MW to 5 MW per turbine. Each wind turbine is electrically attached to a pad-mounted transformer that steps up the voltage to a medium voltage level, typically 34.5 kV.

The collector system is connected at the 34.5 kV level, where the wind turbines are connected to each other in a string or “daisy chain” configuration (Fig. 2). Underground cables are most commonly used in the collector system. Three or more turbines may be connected in this way to trunk lines, which then connect to one of possibly several feeder circuits that use a larger conductor. The collector system is connected to the WPP’s substation transformer. A substation transformer steps up the voltage from a sub-transmission voltage level to a transmission voltage level (60 kV or above).

In the following derivation, we based our equivalent circuit on apparent power losses (i.e., real and reactive power losses). We made the following assumptions to derive the general equation for a circuit within a WPP:

- The current injection from all wind turbines is assumed to be identical in magnitude and angle.
- Reactive power generated by the line capacitive shunts is based on the assumption that the voltage at the buses is one per unit.

B. Connection at the trunk line level

Let’s consider a WPP consisting of different types of wind turbines of different sizes. Consider the equivalent circuit shown in Figure 3 where we have 4 turbines connected in a daisy chain fashion.

Let’s first consider the voltage drops across the line impedances. Across $Z_1$, the voltage drop can be written as:

$$\Delta V_{Z1} = I_1 Z_1 = \left(\frac{S_1}{V}\right) Z_1 = \left(\frac{P_1}{V}\right) Z_1$$

Note that $I_1$ is substituted with $S_1/V$ where $S_1$ is the rated apparent power of wind turbine #1. Based on the assumption that most wind turbines are compensated to have a very close unity power factor, the apparent power $S_1$ can be substituted by the rated power of wind turbine 1, $P_1$. The rest of the equations can be used to describe the voltage drop across $Z_4$ through $Z_4$.

$$\Delta V_{Z2} = (I_1 + I_2) Z_2 = \left(\frac{P_1}{V} + \frac{P_2}{V}\right) Z_2 = \left(\frac{P_1 + P_2}{V}\right) Z_2$$

$$\Delta V_{Z3} = (I_1 + I_2 + I_3) Z_3$$

Figure 2 a) single series daisy-chain physical diagram
b) equivalent representation of circuit (a)

Figure 3. Equivalencing four turbines
(a) Daisy-chain representation
(b) Equivalent circuit representation
\[
(P_1/V + P_2/V + P_3/V)Z_3 = (P_1 + P_2 + P_3)Z_3/V
\]

\[
\Delta V_{Z_4} = (I_1 + I_2 + I_3 + I_4)Z_4 = (P_1/V + P_2/V + P_3/V + P_4/V)Z_4 = (P_1+P_2+P_3+P_4)Z_4/V
\]

Next, we’ll define a new variable, \(P_{Zi}\), as the total power flow in the line segment represented by \(Z_i\).

The power loss in each line segment can be written as:

\[
S_{\text{Loss Z1}} = \Delta VZ_1I_1^* = (P_1/V)(P_1/V)^*Z_1 = P_1^2Z_1/V^2
\]

\[
S_{\text{Loss Z2}} = \Delta VZ_2I_2^* = (P_1 + P_2)^2Z_2/V^2 = P_2^2Z_2/V^2
\]

\[
S_{\text{Loss Z3}} = \Delta VZ_3I_3^* = (P_1 + P_2 + P_3)^2Z_3/V^2 = P_3^2Z_3/V^2
\]

\[
S_{\text{Loss Z4}} = \Delta VZ_4I_4^* = (P_1 + P_2 + P_3 + P_4)^2Z_4/V^2 = P_4^2Z_4/V^2
\]

Note that \(Z_4\) is the last line segment in the daisy chain branch. The total loss can be computed as:

\[
S_{\text{Loss}} = P_{Z1}^2Z_1 + P_{Z2}^2Z_2 + P_{Z3}^2Z_3 + P_{Z4}^2Z_4
\]

From Figure 3b, we can compute the voltage drop across the equivalent impedance as:

\[
\Delta V_{ZS} = I_SZ_S
\]

Where \(I_S = (P_1 + P_2 + P_3 + P_4)/V\)

The total loss in the equivalent impedance can be computed as:

\[
S_{\text{Loss ZS}} = \Delta V_{ZS}I_S^* = I_SI_S^*Z_S
\]

\[
S_{\text{Loss ZS}} = (P_1 + P_2 + P_3 + P_4)^2Z_S/V^2
\]

By equating the loss calculation, we get:

\[
S_{\text{Loss ZS}} = S_{\text{Loss}}
\]

\[
P_{Z4}^2Z_S/V^2 = (P_{Z1}^2Z_1 + P_{Z2}^2Z_2 + P_{Z3}^2Z_3 + P_{Z4}^2Z_4)/V^2
\]

The general expression can be written as:

\[
Z_S = \frac{\sum_{m=1}^{n} P_{Zm}^2 Z_m}{P_{Zn}^2}
\]

C. Shunt representation

Consider an equivalent circuit for the transmission line shown in Figure 4. Because the nature of the capacitance generates reactive power that is proportional to the square of the voltage across them, and considering that the bus voltage is close to unity under normal conditions, the representation of the shunt \(B\) can be considered as the sum of all the shunts in the power systems network. This assumption is close to reality under normal conditions.

With the assumption presented above, we can compute the total shunt capacitance within the WPP as follows:

\[
B_{\text{tot}} = \sum_{i=1}^{n} B_i
\]

D. Pad mount Transformer Equivalencing

Figure 4. Representation of the line capacitance within a wind power plant.
The equivalence of the pad-mounted transformer at the turbine can be derived by using the illustration shown in Figure 5. In Figure 5a, the three-phase step up transformer connected to the wind turbines is shown. The impedance of a single turbine is given. Figure 5b shows the equivalence impedance to represent the entire group of the transformers (in this example, we have 4 turbines).

Next, we must consider parallel branches connected to the same nodes, as shown in Figure 5. Each branch has unique impedance and is connected to a wind turbine. Let’s consider a simple daisy chain of four turbines of different sizes connected to the same node.

- Originally, each turbine has its own transformer with different ratings.
- All turbines are producing at rated output.
- The transformer impedances for each turbine are \( Z_{T1}, Z_{T2}, Z_{T3}, Z_{T4} \), respectively.

Now let’s consider the voltage drops across the line impedances. Note that \( I_1 \) is substituted with \( S_1/V \) where \( S_1 \) is the apparent power of wind turbine #1. Based on the assumption that each turbine generates equal current in magnitude and phase angle, and wind turbines are compensated to have a very close to unity power factor, the apparent power \( P_1 \) can be substituted by the rated power of wind turbine #1, \( P_1 \). The rest of the equations can be used to describe the voltage drop across \( Z_{T1} \) through \( Z_{T4} \).

Across \( Z_{T1}, Z_{T2}, Z_{T3}, Z_{T4} \), the voltage drops can be written as:

\[
\Delta V_{ZT1} = I_1 Z_1 = \frac{(S_1/V)}{Z_1} = \frac{P_1}{V}
\]

\[
\Delta V_{ZT2} = (P_2/V) Z_2
\]

\[
\Delta V_{ZT3} = P_3 Z_3/V
\]

\[
\Delta V_{ZT4} = P_4 Z_4/V
\]

Losses in individual transformer:

\[
S_{Z1} = \Delta V_{ZT1} I_1^* = P_1 Z_{T1}/V (P_1/V)^* = P_1 Z_{T1}/V (P_1/V)^* = P_1^2 Z_{T1}/V^2
\]

\[
\Delta V_{ZTS} = \{(P_1+P_2+P_3+P_4)/V\} Z_{TS} = \{(P_1+P_2+P_3+P_4)/V\} \frac{Z_{TS}}{V}
\]

Turbine #1

\[ I_1 \]

\[ Z_{T1} \]

I_4

I_S

Figure 5. Equations for finding the equivalence of parallel connection of four turbines of different sizes.

\[ = \{P_{Tot}/V\} Z_{TS} \]

\[ S_{Z2} = P_2^2 Z_{T2}/V^2 \]

\[ S_{Z3} = P_3^2 Z_{T3}/V^2 \]

\[ S_{Z4} = P_4^2 Z_{T4}/V^2 \]

The total loss is:

\[ S_{ZS} = \Delta V_{ZTS} I_S^* = P_{Tot}^2 Z_{TS}/V^2 \]

By substitution, we derived the following equations:

\[ P_{Tot}^2 Z_{TS}/V^2 = P_1^2 Z_{T1}/V^2 + P_2^2 Z_{T2}/V^2 + P_3^2 Z_{T3}/V^2 + P_4^2 Z_{T4}/V^2 \]

The general expression can be written as:

\[ Z_{TS} = \frac{\sum_{m=1}^{n} P_m^2 Z_{Tm}}{\sum_{m=1}^{n} P_m^2} \]
III. WIND TURBINE GROUPING

In this section, a method for grouping of turbines will be explored.

A. Groupings based on the diversity of the WPP

This grouping criterion is based on the diversity generally found in a very large WPP. For a very large WPP, the area within the power plant is very large. The number of turbines within the WPP can be a very high number, and sometimes it is not easy to get the same types of turbines due to limited supply. Or the WPP is expanded due to re-powering program.

- Diversity in wind speed: instantaneously, the wind speed at one corner of the WPP might be significantly different from the wind speed at the other corner of the WPP. Similarly, altitude diversity may be found in a large WPP which will lead to differences in wind speeds experienced by each wind turbine.

- Diversity in line impedance: in some WPPs, especially with significant diversity in the altitudes (WPPs with many hills), the locations of turbines are chosen based on the best wind resource. Thus, groups of turbines will be installed on top of one hill with significant distance with respect to the other groups of turbines. This diversity creates significant diversity in the size of the impedances connecting the groups of turbines to the point of interconnection.

- Diversity in turbine types: if there are almost equal numbers of different turbines types, it is appropriate to represent each turbine type within the WPP.

- Diversity in control algorithms: even within the same type, there could be different control algorithms implemented, thus creating groups of turbines with different response to the same excitations. For example, for Type 3 and Type 4 turbines, the wind turbine can be controlled to operate in Voltage Control mode or in Power Factor mode.

B. Groupings based on the transformer size

This is a convenient way to group wind turbines within large WPPs. WPP sizes are getting larger and larger. Presently, a 300-MW WPP size is considered a norm. The step-up transformer used however, is normally divided into smaller sizes for economic, reliability, and redundancy reasons. A 30 to 60-MVA transformer is commonly used to step up the voltage of a group of turbines. This method of grouping will probably be the most common type of grouping used in most new power plant cases.

C. Groupings based on the short circuit capacity

For a very large WPP, a single turbine representation (STR) or multiple turbine representation (MTR) should be used. MTR is chosen if there is a significant diversity within the WPP in terms of type of wind turbines, impedance levels of the line feeder, different control algorithms, or different wind turbine manufacturers.

In many cases, newer WPPs are represented by a single wind turbine representation because the wind developer usually chooses the same type of wind turbine within the same WPP. If multiple turbine representation is chosen, the WPP must be represented by several wind turbines. Each wind turbine represents a group of turbines with the same characteristics. The number groups within a single WPP can be determined based on the size of the generated rated power of the group.

A WPP connected to a grid with multiple wind turbine representation must be represented by groups of wind turbines. Since Short Circuit Capability (SCC) determines the level of grid stiffness, which also governs its stability characteristic (both voltage and phase angle), and the impact of the WPP on the power grid, it is convenient to express the grouping of the wind turbines by its group size in percentage of its SCC at the point of interconnection. For example, a 150-MW WPP might include 75 MW of turbine Type 1, 5 MW of turbine Type 2, 60 MW of turbine Type 3, and 10 MW of turbine Type 4. With the system base of 100 MVA and the grid has an SCC=5, and, there are four groups of wind turbines within a 150MW WPP. In terms of its SCC, we can divide the group of turbines into:

- Type 1: $75/(5*100) = 15\%$ SCC
- Type 2: $5/(5*100) = 1\%$ SCC
- Type 3: $60/(5*100) = 12\%$ SCC
- Type 4: $10/(5*100) = 2\%$ SCC

Note that the impact of Type 4 wind turbine generators (WTGs) is very small (1%SCC) compared to the impact of Type 1 WTGs. In this case, it might be useful to combine Type 4 into another group with similar characteristics. From the nature of its behavior, we recommend that Type 1 and Type 2 be considered to have similar behavior, and Types 3 and 4 be considered to have similar behavior. We do not recommend combining Type 1 and Type 3, or Type 2 and Type 3, or Type 2 and Type 4, or Type 1 and Type 4. By regrouping Type 2 turbines into the Type 1 group as shown in the example below, the number of turbine representations can be reduced, thus simplifying the calculation.

- Type 1: $80/500 = 16\%$ SCC
- Type 3: $60/500 = 12\%$ SCC
- Type 4: $10/500 = 2\%$ SCC
The planner may decide that a group of wind turbines with a total output power of less than 5% of the SCC can be combined into a group with a similar type of turbines to reduce the number of turbine representations. In this case, for a stiffer grid, the grouping allocation will change.

For example, the above list of groups can be rewritten for SCC = 10 as follows:
- Type 1: 75/1000 = 7.5% SCC
- Type 2: 5/1000 = 0.5% SCC
- Type 3: 60/1000 = 6% SCC
- Type 4: 10/1000 = 1% SCC

Which can be simplified into:
- Type 1: 80/1000 = 8% SCC
- Type 3: 70/1000 = 7% SCC

This can be considered to be the simplest form of wind turbine representation without losing the significant characteristics of the major turbine contributions. The proportion of the wind turbine types representing the turbine group indicates the influence of the WPP on the power grid (i.e., WPP with the stiffer grid will have a lower impact on the power grid).

IV. CASE STUDY: MULTIPLE TURBINE REPRESENTATION

In this section an example of equivalencing a WPP is presented in Figure 6. This WPP consists of non-uniform turbines. In this power plant, only two kinds of wind turbines will be considered; 1 MW of Type 1 (fixed-speed induction-generator wind turbine) and 3 MW of Type 4 (variable-speed wind turbine with full power converter).

The basic assumptions used in the equivalencing method are:
- assume that all turbines generate rated power at rated current
- equate the losses within the branch to the total losses
- find the equivalence impedance
- assume that inter-turbine cables required is equal to 400 feet.

Since we are interested only on the impedance between two turbines, and, for the simplicity, we use 400 feet as the distance between two turbines. This number is sufficient for the unit turbine chosen 3.16 MW (distance between this two turbines is more than 3 times blade diameter).

In this equivalencing method, the calculation for impedance is taken from the data provided (based on the cable chosen). Using the collector medium voltage of 34.5 kV as our base voltage, and the base apparent power of 100 MVA, we can find the base impedance $Z_{\text{base}}$ in Table I.

Figure 6. Groups of turbines within a wind power plant.
The typical values of the underground cable and overhead wire impedance in ohms and in per unit are given in Table 2.

As shown in Figure 6, the WPP is divided into 9 groups of turbines connected in daisy chain fashion. The number of turbines within each group varies from 3 to 8 turbines.

From this layout, we can configure the WPP into four turbine representations. Different geometrical shapes are used to form the boundary of each turbine representation.

There are two types of turbines installed in this WPP. One type of turbine is a Type 1 WTG rated at 1 MW, and another type is Type 4 WTG with a rating of 3 MW.

Two major feeders connect the groups of turbines to two transformers. The first feeder connects the three turbine representations; the rectangle representation, the circle representation, and the diamond representation. Another feeder connects the groups of turbines enclosed by the ellipse shape.

The turbine representation enclosed the ellipse (from G6 through G9) are connected to this feeder. Each group consists of three to four turbines and each turbine is rated at 3 MW of Type 4 turbines.

Table 1, representation of the other turbines bounded by rectangle, diamond, and ellipse can be derived.

Table 6 contains the impedances of overhead lines interconnecting the rectangle, circle, diamond, and ellipse shapes, and the substation transformer shown in Figure 6.

The summary of the calculations for the collector system representation is presented in the Table 4 and Table 5. From Tables 4, 5, and 7, we can draw the four turbine representations of the WPP shown in Figure 7.

The calculations to convert from the “four turbine representation” as shown in Figure 7 into the “two turbine representation” as shown Figure 8 are listed in Appendix 1.

V. CONCLUSION

This paper describes methods used to represent WPPs by equivalence. For various reasons, some WPPs are built with different wind turbines. This diversity of WPPs needs to be represented.

One important aspect of equivalencing is to find a way to group wind turbines into larger group that sufficiently represents the overall characteristics of the WPPs. In section III, several methods of grouping is presented.

As an example, a case study of a WPP (100 MW) with two substation transformers is presented. Step–by–step equivalencing of the impedances and shunt capacitances is shown to represent the WPP into a four-turbine representation. Further reduction into a two-turbine representation is also shown.

Finally, the decision to represent the WPP in a power system study depends on the power system planners. Any major diversity in the WPP with major contributions to the total output power of the WPP should be represented in the WPP model.

VIII. BIOGRAPHIES

Eduard Muljadi received his Ph. D. in Electrical Engineering from the University of Wisconsin, Madison. From 1988 to 1992, he taught at California State University, Fresno, CA. In June 1992, he joined the National Renewable Energy Laboratory in Golden, Colorado. His current research interests are in the fields of electric machines, power electronics, and power systems in general with emphasis on renewable energy applications. He is member ofEta Kappa Nu, Sigma Xi and a Senior Member of IEEE. He is involved in the activities of the IEEE Industry Application Society (IAS), Power Electronics Society, and Power Engineering Society (PES). He is currently a member of Industrial Drives Committee, Electric Machines Committee, and Industrial Power Converter Committee of the IAS, and a member of Working Group on Renewable Technologies and Dynamic Performance Wind Generation Task Force of the PES. He holds two patents in power conversion for renewable energy.

Subbaiah Pasupulati graduated from University of Texas, Arlington with M.S. in Electrical Engineering in 2003. From 2003 to 2005, he was with Energy Unlimited Inc., a Wind Power Plant in Palm Spring, California where he was responsible to oversee the operations of the plant. He joined Oak Creek Energy System Inc. (OCES) in 2006. He is currently the Power System Engineer at OCES, he involved in design and development of 2.5 GW plus wind power plants in the Tehachapi area. He participated in California Southern Regional Transmission Plan 2006 conducted by California Independent System Operator which came up with Tehachapi’s Renewable Transmission Plan. He is a member of the IEEE. He is an active member of WECC’s Technical Studies Subcommittee & Wind Generator Modeling Group

Abraham Ellis graduated from New Mexico State University in 2000 with a Ph.D. in Electrical Engineering. In 2001, he joined the Transmission Operations Department at Public Service Company of New Mexico, where he works in the areas of large generator interconnection studies, transmission expansion planning and special projects related to transmission system performance and monitoring. Abraham is involved with various activities related to wind energy at the regional and national level. He currently coordinates Western Electricity Coordinating Council’s Wind Generator Modeling Group and the IEEE Wind Generator Dynamic Performance Task Force. He also served as Chairman of the Modeling and Validation Work Group until July 2007. Abraham is a Senior Member of IEEE and is a registered Professional Engineer in the State of New Mexico.

Dmitry Kosterov received Ph.D. from Oregon State University in 1996. Dr.Kosterov is currently with Bonneville Power Administration, where his responsibilities include transmission planning, power system modeling, and power system controls. Dr.Kosterov was involved in analysis and model validation of 1996 outages that occurred in the Western Interconnection. Dr.Kosterov has been involved in testing, model validation, and dynamic performance monitoring of a number of hydro- and thermal- power plants in Pacific Northwest. Dr.Kosterov led WECC Generator Testing Task Force through development and approval of Generating Unit Model Validation Policy in 2006. Dr.Kosterov is a chair of WECC Modeling and Validation Work Group and WECC Load Modeling Task Force. Dr.Kosterov received Eugene Starr award for technical excellence from BPA Administrator in 2005.
